Option Hedging with Smooth Market Impact

Tianhui Michael Li* and Robert Almgren†

June 11, 2015

Abstract
We consider a large investor hedging a long or short options position, whose trades generate adverse market impact. Unlike the complete-market or proportional transaction cases, the agent no longer finds it tenable to be perfectly hedged or even within a fixed distance of being hedged. Instead, he may find himself arbitrarily mishedged and optimally trades towards the classical Black-Scholes delta, with trading intensity proportional to the degree of mishedge and inversely proportional to illiquidity. Option hedging activity should cause a measurable increase or decrease in realized volatility, depending on whether sell-side traders are net long or short options. We illustrate the instability that can arise if the hedge strategy is applied carelessly with discrete time steps, and give a discrete-time formulation that avoids this instability.

1 Introduction

Dynamic hedging of an option position is one of the most studied problems in quantitative finance. However, when the position size is large, the optimal hedge strategy must take account of the transaction costs that will be incurred by following the Black-Scholes solution. In addition to private costs, hedging activity by one or more large position holders may have observable effects on the public markets.

On the morning of July 19, 2012, an unusual “sawtooth” pattern was observed in US equity markets. Four large stocks—McDonald’s (MCD), Coca-Cola (KO), IBM (IBM), and Apple (AAPL)—exhibited substantial price swings on a regular half-hour schedule [Hwang et al., 2012]. Until about 1:30 PM, each stock hit a local minimum price on each hour, and a local maximum on each half-hour (Figure 1). No significant news was released on this day, but CBOE options expiration was the next day. The most plausible explanation [Lehalle and Lasnier, 2012] is that these patterns were the result of a delta-hedging strategy executed by a large options position holder with no regard for market impact. Each half-hour, he or she evaluated the necessary trade to obtain a delta-neutral position, and executed this trade across the next half-hour. Market impact caused the price to move, and at the next evaluation at the new price, the position was partially reversed. The action was similar to a forward Euler discretization of an ordinary differential equation [Ascher and Petzold, 1998] which can introduce instability into a stable problem.

As an additional example, on Oct. 15, 2014, the US Treasury market underwent the largest intraday move since 2009 [Almgren, 2015]. Devasabai [2014] cites numerous market participants who attribute the market instability in part to hedging of large short option positions held by the dealer community: “These things don’t happen unless there is a big short gamma position,” says a senior fixed-income portfolio manager at a firm in New York.” This paper explains how this hedging activity can increase market volatility.

In this paper we use a simple market impact model similar to those used for optimal execution to study the hedging problem faced by a large investor. The optimal hedge strategy depends on a balance between the investor’s risk aversion and temporary market impact, which determines how much he or she is willing to pay in transaction costs to reduce hedging error. Permanent market impact causes an observable effect on the public market price, leading to an increase or decrease in realised volatility depending on whether the large investor, or the entire community of traders who hedge their position, are net long or short options. A simplistic implementation of the hedge strategy in discrete time intervals can lead to the behavior shown in Figure 1, but in Section 3.5 we show how to stably execute such hedging.

There is a substantial literature on the effect of transaction costs on Black-Scholes hedging. Leland [1985] introduced a discrete-time model in which the trading within each time interval affected the market price at the next interval. With suitable dependence of the market impact on the time interval, he was able to obtain a preference-free option price calculated using a modified implied volatility. Subsequent work [Kabanov and Safarian, 1997, Zhao and Ziemba, 2007] has clarified some aspects of Leland’s model, but the essential ingredient remains a suitable limit of discrete hedging. See Kabanov and Safarian [2009] for a full discussion.

More recent literature is interested in super-replication [Çetin et al., 2010, Soner et al.,
Figure 1: Price swings for Coca-Cola (KO) on Thursday, July 19, 2012, one day before options expiration. These were likely caused by a naïve hedge strategy for a large options position.

Our paper relaxes this requirement by having a finite penalty for being mishedged. Our paper is more closely linked to these using a utility-based framework [Cvitanić and Wang, 2001].

Transaction costs themselves have been modeled via various mechanisms. A large strand of the literature models trading frictions as a cost proportional to trade size, typically interpreted as arising from the bid-ask spread. This branch of the literature uses singular control and the optimal solution is typically in the form of a tracking band [Davis and Norman, 1990, Shreve and Soner, 1994]. As the portfolio exits this band, the trader makes singular corrections to his holdings to keep it strictly within the limits of the band. In the upper panel of Figure 2, we illustrate this hedging strategy.

Our simple market impact model is phenomenological and not directly based in the details of microstructure. Following Almgren and Chriss [2000], we decompose price impact into temporary and permanent price impact. We can think of the temporary impact as connected to the liquidity cost faced by the agent while the permanent impact as linked to information transmitted to the market by the agent’s trades. The temporary impact depends on the rate of execution, while the permanent impact depends on the total number of shares executed. Under this model, the optimal solution is to trade aggressively towards being hedged, taking account both the available liquidity and the degree of the mishedge. Our trading strategy is smooth: we approximate the impact-free Black-Scholes
Figure 2: Comparison of the proportional-transaction-cost fixed-tracking-band strategy (top) and our dynamic strategy (bottom). In the former, our (green) trading position changes only when the (blue) target leaves the (gray) trading-band. In the latter, our (green) trading position smoothly adjusts to the same (blue) target. Compare the smooth trading flow and position of the latter strategy to the abrupt trading of the former.

Delta, an infinite variation process, with trading positions that are differentiable. In Figure 2 we compare our strategy to the strategy using a tracking band.

Our solution is similar to that of Gârleanu and Pedersen [2013], who solve the infinite-horizon “Merton Problem” under only temporary market-impact assumptions. As in our setup, they use a linear-quadratic objective rather than the traditional expected utility setup. They find that trading intensity at time $t$ is given by

$$\theta_t = -\kappa h \cdot (X_t - \text{target}_t),$$

where $X_t$ is the number of shares, $\kappa$ is an urgency parameter with units of inverse time, $h > 0$ is a dimensionless constant of proportionality, and the “target portfolio” target$t$ is related to the frictionless Merton-optimal portfolio. The intensity of trading $\theta_t$ is proportional to the distance between the current holdings and target, and is inversely proportional to the square root of the illiquidity coefficient. Rogers and Singh [2010] obtain a similar solution for option hedging, with temporary impact but no permanent impact, in which the coefficient $h$ depends on time to expiration.
In our model, and that of Rogers and Singh [2010], the target portfolio is effectively the Black-Scholes delta $\Delta_t$, at least for options with approximately constant $\Gamma$, so that the value is symmetric around the local value. This suggests that we can think of delta-hedging in an illiquid market as a Merton optimal investment problem where the Merton portfolio is the Black-Scholes hedge portfolio. For more general options, the target portfolio has an extra term accounting for the non-zero third derivative with respect to spot of the Black-Scholes option price.

Guéant and Pu [2015] have solved a model very similar to ours, including both temporary and permanent price impact. Their focus is on the modifications to the option value introduced by market impact, whereas a central focus of our paper is the likely effects to be observed in the public market. We also concentrate on a few special cases in which exact solutions can give insight, whereas they undertake numerical solution in more general cases.

Lions and Lasry [2006, 2007] have studied the effect on volatility of hedging by a large options trader. In our language, they include permanent impact but not temporary. Thus the trader’s position is always perfectly hedged, but there is an observable effect on the realised volatility. In our model, this modified volatility appears on time scales longer than the hedge scale, which is controlled by risk aversion and temporary impact.

Avellaneda and Lipkin [2003] have studied “stock pinning:” the tendency of the underlying asset price to approach an option strike price at expiration. They use a model similar to ours, but their analysis is based on a local approximation near expiration at the money. Jeannin et al. [2008] have performed a more refined analysis, and determine a modified volatility coefficient near expiration.

The subsequent sections are as follows. We motivate our assumptions and formally set up the problem in Section 2. In Section 3.1 we present the general solution approach. We solve this problem for a quadratic option value in 3.2, and in 3.3 we consider the impact of hedging on the price process. In 3.4 we consider the special case of no permanent impact, which we can solve for general option structure. In 3.5, we give a stable discrete-time solution, that avoids the problems shown in Figure 1. Finally, in Section 4 we summarize and suggest possible future empirical work.

2 Problem Setup

We first present our market model including both temporary and permanent impact. We then discuss hedging of a European option, and present our objective function possibly including overnight risk.

2.1 Market Impact Model

Let $X_t$ be the number of shares held by the agent at time $t \geq 0$. The fundamental price at $t$ is given by

$$P_t = P_0 + \nu (X_t - X_0) + \sigma W_t$$

where $\nu > 0$ is the coefficient of permanent impact, $\sigma > 0$ is the absolute volatility of the fair value, and $W_t$ is a standard Brownian motion with filtration $\mathcal{F}_t$. Using arithmetic
Brownian motion rather than geometric is appropriate over the short time horizons considered in the paper and leads to dramatic simplifications. We neglect interest rates and dividends. Lions and Lasry [2006, 2007] considered option hedging for a large trader who faces this form of permanent impact, but with no temporary impact.

Under this model, if a position of size $X_0$ shares with initial market price $P_0$ is fully liquidated, the expected value of the resulting cash will be $\int_0^X (P_0 - \nu x) \, dx = X_0 P_0 - \frac{1}{2} \nu X_0^2$, independently of the time taken or strategy used to execute the liquidation. That is, we cannot avoid a cumulative impact cost of $\frac{1}{2} \nu X_0^2$, quadratic in portfolio size. Nonetheless, we shall assume that such a position is marked to market at value $X_0 P_0$.

We denote by $\theta_t$ the instantaneous intensity of trading, so that

$$X_t = X_0 + \int_0^t \theta_u \, du.$$  

Implicit in this formulation is the assumption that the trade rate $\theta_t$ is pointwise defined and bounded, and hence that the portfolio position $X_t$ is differentiable. As in Almgren and Chriss [2000], trading at instantaneous rate $\theta_t$ requires payment of a price premium linear in $\theta_t$. That is, the effective trade price is

$$\tilde{P}_t(\theta_t) = P_t + \eta \theta_t.$$  

where $\eta > 0$ is the coefficient of temporary impact. Nonlinear temporary impact functions are more consistent with empirical data [Almgren et al., 2005] but would complicate our analysis; they have been used for stock pinning by Avellaneda et al. [2012]. Rogers and Singh [2010] considered option hedging with this form of temporary impact, but with no permanent impact.

### 2.2 European Option

We think of hedging a European contingent claim (option) over a finite time horizon $[0, T]$. The end time $T$ need not be the option expiration date, and in fact we shall usually think of it as the end of the current trading day, so that our problem is intraday hedging. Let $g(t, p)$ denote the value of the option for a small trader in a complete market whose execution has no price impact. The agent’s total portfolio value at time $t$ is $X_t P_t + g(t, P_t)$.

If the option value at $t = T$ is specified as $g_0(p)$, then the no-impact option value for $t \in [0, T)$ is the solution of the Black-Scholes partial differential equation

$$\dot{g}(t, p) + \frac{1}{2} \sigma^2 g''(t, p) = 0 \quad \text{for } t, p \in [0, T) \times \mathbb{R} \quad \text{and} \quad g(T, p) = g_0(p).$$  

Here $\dot{g}$ is derivative with respect to $t$ and $g'$ and $g''$ are derivatives with respect to $p$.

We identify the Black-Scholes delta and gamma

$$\Delta(t, p) = -g'(t, p),$$

$$\Gamma(t, p) = g''(t, p).$$

The negative sign on $\Delta(t, p)$ is because our trader is long the payoff, rather than hedging a short position; a perfectly hedged portfolio will have $X_t = \Delta(t, P_t)$. A trader who is long
a call option or short a put will have $\Delta < 0$; one who is short a call or long a put will have $\Delta > 0$. A trader who is long a put or call option will have $\Gamma > 0$; a trader who is short will have $\Gamma < 0$. Thus $\Gamma$ reflects both the sign and size of the trader’s net option position.

We assume that the option is such that

$$\Gamma(t, p) = g''(t, p)$$

is uniformly bounded above and below, and is Lipschitz in $p$ with a constant that is independent of $t$. (4)

This assumption holds for most options except at expiry, and so this formula will be valid for intraday hedging except on the expiration day.

We also assume that permanent impact $\nu$ is small enough that

$$\text{There is a constant } G > 0 \text{ with } 1 + \nu \Gamma(t, p) \geq G \text{ for all } (t, p).$$

(5)

For an option contract having $\Gamma < 0$ and a fixed value of $\nu$, condition (5) can always be violated by scaling up the position size. Thus our model is meaningful in an intermediate range, where the position is large enough to have some effect on the market, but not so large that option hedging completely dominates the intrinsic market dynamics. We expect $|\nu \Gamma| \ll 1$, so option hedging is not the primary factor driving the price process.

To motivate (5), suppose that the current asset price is $P_t$, and we are imperfectly hedged so that $X_t \neq \Delta(t, P_t)$. Suppose that we ignore temporary impact, so we would be able to execute an instantaneous trade to an arbitrary new position $\hat{X}_t$. With permanent impact, the price following this trade will be $\hat{P}_t = P_t + \nu(\hat{X}_t - X_t)$, and we want to have $\Delta(t, \hat{P}_t) = \hat{X}_t$ to be hedged against small price fluctuations. We may write the hedge condition as

$$F(\hat{X}_t) = \Delta(t, P_t) - X_t \quad \text{with} \quad F(\hat{X}_t) = \hat{X}_t - X_t + \int_{P_t}^{P_t + \nu(\hat{X}_t - X_t)} \Gamma(t, p) \, dp.$$  

(6)

Condition (5) says that $F'(\hat{X}_t) = 1 + \nu \Gamma \geq G > 0$ everywhere, so there always exists a unique optimal hedge portfolio. Temporary impact $\eta$ will control the rate at which we trade towards this target. If $\Gamma > 0$ then $F'(\hat{X}_t) > 1$ and our trading moves the price toward our hedge target: permanent impact makes hedging easier. If $\Gamma < 0$ then our trading pushes the price away and hedging is hard.

### 2.3 Wealth dynamics

We assume that our trader’s position is marked to market using the Black-Scholes option value, as well as the book value for the underlying shares, ignoring market impact that would be incurred in converting these positions into cash. This could be the case, for example, because of institutional rules. Thus we define the initial and terminal wealth

$$R_0 = g(0, P_0) + X_0 P_0$$

$$R_T = g(T, P_T) + X_T P_T - \int_0^T \hat{P}_t(\theta_t) \theta_t \, dt$$

(6)
where the last term in (6) denotes the capital spent or gained from trading. Integrating by parts, using the stock dynamics (1), the total temporary impact (2), and Feynman-Kac (3), these quantities are related by

\[
R_T = R_0 + \int_0^T Y_t dP_t - \eta \int_0^T \theta_t^2 dt
= R_0 + \sigma \int_0^T Y_t dW_t + \nu \int_0^T Y_t \theta_t dt - \eta \int_0^T \theta_t^2 dt,
\]

in which the portolio’s instantaneous net delta exposure is

\[
Y_t = X_t - \Delta(t, P_t) = X_t + g'(t, P_t).
\]

The final wealth \( R_T \) is the sum of the fluctuation during the trading day and the liquidity cost from permanent and temporary impacts. For a Black-Scholes hedged portfolio, \( Y_t = 0 \). But since \( g'(t, P_t) \) is typically of infinite variation in \( t \) while \( X_t \) must be differentiable with the temporary impact (2), perfect hedging is impossible.

### 2.4 Mean-variance optimization

The trader’s goal is to choose the strategy \( \theta_t \) so as to maximise the value of the final wealth \( R_T \) (6). With no market impact, classic Black-Scholes theory says that we may maintain \( Y_t = 0 \), thereby eliminating all randomness in \( R_T \) due to market fluctuations \( dW_t \); the zero-risk solution is independent of risk tolerance. With market impact, perfect hedging is impossible and we must maximise the expected value of \( R_T \), while also minimizing its uncertainty due to some risk aversion criterion.

We choose to use a mean-variance criterion rather than a utility function. Although mean-variance optimization occasionally can have unexpected properties, it is extremely straightforward and familiar to practitioners. The expected value of \( R_T \) is

\[
\mathbb{E}R_T = R_0 + \nu \mathbb{E} \int_0^T Y_t \theta_t dt - \eta \mathbb{E} \int_0^T \theta_t^2 dt.
\]

The variance of \( R_T \) is complicated, since all terms in (6) are random and dependent. But a reasonable approximation is that the largest source of uncertainty is the price motions. The terms involving market impact are important because they have consistent sign, but their variances are small compared with market dynamics. This is the “small-portfolio” approximation of Lorenz and Almgren [2011] and further explored by Tse et al. [2013]. Thus we make the approximation

\[
\text{Var } R_t \approx \sigma^2 \text{Var } \int_0^T Y_t dW_t = \sigma \mathbb{E} \int_0^T Y_t^2 dt.
\]

Then, introducing a risk aversion coefficient \( \lambda > 0 \), we define our mean-variance objective function to be the approximate version of \( \lambda \text{Var } R_T - \mathbb{E}R_T \) or

\[
\inf_{\theta \in \Theta} \mathbb{E} \left[ \lambda \sigma^2 \int_0^T Y_t^2 dt - \nu \int_0^T Y_t \theta_t dt + \eta \int_0^T \theta_t^2 dt \right].
\]
where the control set \( \Theta \) is given by
\[
\Theta = \left\{ \theta \text{ predictable, with } \mathbb{E} \int_0^T \theta_s^2 ds < \infty \text{ and } \theta_t \leq C(1 + |Y_t|) \text{ a.s. for all } t \right\}.
\]
This can be thought of as a finite-horizon adaptation of Gârleanu and Pedersen [2013].

The state variables have dynamics
\[
\begin{align*}
dP_t &= \nu \theta_t dt + \sigma dW_t \quad (8) \\
dY_t &= (1 + \nu \Gamma(t; P_t)) \theta_t dt + \sigma \Gamma(t; P_t) dW_t \quad (9)
\end{align*}
\]
where the same Brownian process \( W_t \) appears in both (an Itô term in \( \dot{g} \) cancels using (3)).

It is easy to see that \( P_t \) is a continuous semimartingale and hence predictable. Since we assume \( \Gamma \) bounded, \( Y_t \) is well-defined for all \( \theta \in \Theta \). Each share purchased (\( \theta_t dt \)) pushes \( P_t \) up by \( \nu \) because of the permanent impact, and also increases the net delta position \( Y_t \) by \( 1 + \nu \Gamma(t; P_t) \): 1 for the increase in the stock position and \( \nu \Gamma(t; P_t) \) for the effect of permanent price impact effect on the underlying price and hence the option’s delta.

2.5 Overnight risk

In the above formulation, trading continues until time \( T \) when the position is marked to market. In an extension of the model, we may suppose that \( T \) represents the end of the trading day, but market risk is incurred until tomorrow’s open \( T_* > T \). The trader must choose his or her close position \( X_T \) to hedge this overnight risk as much as possible.

Between \( T \) and \( T_* \), the agent is not allowed to trade, so \( X_{T_*} = X_T \) but the underlying price continues to evolve. As in (6),
\[
\begin{align*}
R_{T_*} &= g(T_*, P_{T_*}) + X_T P_{T_*} - \int_0^T \dot{P}_t(\theta_t) \theta_t dt \\
&= R_T + g(T_*, P_{T_*}) - g(T, P_T) + X_T (P_{T_*} - P_T) \\
&= R_T + \int_T^{T_*} [g'(t; P_t) - g'(T; P_T)] dP_t + Y_T (P_{T_*} - P_T) \\
&= R_T - \xi + Y_T \Pi
\end{align*}
\]
with
\[
\begin{align*}
\xi &= \int_T^{T_*} (\Delta(t; P_t) - \Delta(T, P_T)) dP_t \\
\Pi &= P_{T_*} - P_T.
\end{align*}
\]
Each of \( \xi \) and \( \Pi \) has expected value 0, and so the modified objective function is
\[
\begin{align*}
\inf_{\theta \in \Theta} \mathbb{E} \left[ \lambda (Y_T \Pi - \xi)^2 + \lambda \sigma^2 \int_0^T Y_t^2 dt - \nu \int_0^T Y_t \theta_t dt + \eta \int_0^T \theta_t^2 dt \right].
\end{align*}
\] (10)

More generally, we may abstract from the details of the overnight price process to consider any \( L^2 \) random variables \( \xi \) and \( \Pi \) of mean zero, measurable on \( \mathcal{F}_T \), such that the
distribution of $\xi$ depends only on $P_T$, and the distribution of $\Pi$ is independent of $\mathcal{F}_T$. We denote $\Sigma^2 = \mathbb{E}\Pi^2$, which is $\sigma^2(T_* - T)$ in the Brownian case, and $\Xi^2 = \mathbb{E}\xi^2$.

We shall use (10) as our objective function from now on, recovering the previous case by setting $\xi \equiv \Pi \equiv 0$.

**Example** We could take $T$ to be the maturity of the option (ignoring the unboundedness of $\Gamma$ if $P_t$ is near the strike). In this case, there is no risk beyond expiration and formally $\xi$ and $\Pi$ would be zero. But the individual trader may choose to incorporate a penalty in order to drive the portfolio toward more precise hedging at expiration.

**Example** On intraday trading time scales, far from expiration, it is plausible to model the option as having a constant gamma, $\Gamma(t, p) \equiv \Gamma \in \mathbb{R}$ constant, so

$$\Delta(t, P_t) = \Delta(T, P_T) - \Gamma (P_t - P_T).$$

(11)

If $\xi$ and $\Pi$ arise from the Brownian price process continued on $T < t < T_*$, then

$$\xi = -\Gamma \int_T^{T_*} (P_t - P_T) dP_t = -\frac{1}{2} \Gamma \left( \Pi^2 - \Sigma^2 \right).$$

The two terminal terms are uncorrelated:

$$\mathbb{E}[\xi \Pi | P_T] = 0$$

and the terminal objective term would be

$$\mathbb{E} \left[ \lambda \left( Y_T \Pi - \xi \right)^2 \right] = \lambda \left( \Sigma^2 Y_T^2 + \Xi^2 \right).$$

(12)

For general $\xi$ and $\Pi$, “constant $\Gamma$” includes the assumption that the distribution of $\xi$ as well as $\Pi$ is independent of $\mathcal{F}_T$ and that $\xi$ and $\Pi$ are uncorrelated.

## 3 Solution

We now use standard techniques of optimal control to identify the partial differential equation satisfied by the value function, and we exhibit solutions in two special cases.

### 3.1 HJB equation

Let $J(t, p, y)$ denote the optimal value function beginning at time $t$:

$$J(t, p, y) = \inf_{\theta \in \Theta_t} \mathbb{E} \left[ \lambda \left( Y_T \Pi - \xi \right)^2 + \lambda \sigma^2 \int_t^T Y_s^2 ds - \nu \int_t^T Y_s \theta_s ds + \eta \int_t^T \theta_s^2 ds \right]$$

where $\Theta_t$ denotes the allowable control set $\theta_s$ for $t \leq s \leq T$, and the expectation is conditional on initial values $P_t = p$ and $Y_t = y$. The actual share holding $X_t$ does not enter into the trading cost on the remaining time, only the mishedge $Y_t$. We temporarily
assume that $J \in C^{1,2,2}([0, T] \times \mathbb{R} \times \mathbb{R})$. Then from the Martingale Principle of Optimal Control, $J$ must satisfy the HJB equation

$$0 = J_t + \lambda \sigma^2 y^2 + \frac{1}{2} \sigma^2 J_{pp} + \Gamma \sigma^2 J_{p y} + \frac{1}{2} \Gamma^2 \sigma^2 J_{yy} + \inf_{\theta \in \mathbb{R}} \left\{ \left[ (1 + \nu \Gamma) J_y + \nu J_p - \nu y \right] \theta + \eta \theta^2 \right\}$$

in which subscripts on $J$ denote partial derivatives (subscripts $t, T$ on $\theta, X, P$, etc. continue to denote evaluation at the given time), and $\Gamma = \Gamma(t, p)$. The optimal strategy is

$$\theta = -\frac{1}{2\eta} \left[ (1 + \nu \Gamma) J_y + \nu J_p - \nu y \right]$$

and hence the value function satisfies

$$0 = J_t + \lambda \sigma^2 y^2 + \frac{1}{2} \sigma^2 J_{pp} + \Gamma \sigma^2 J_{p y} + \frac{1}{2} \Gamma^2 \sigma^2 J_{yy} - \frac{1}{4\eta} \left[ (1 + \nu \Gamma) J_y + \nu J_p - \nu y \right]^2$$

with terminal data

$$J(T, p, y) = \lambda \mathbb{E} (y \Pi - \xi)^2.$$  

In the expectation, the distribution of $\xi$ is conditional on $P_T = p$; recall that $\Pi$ is assumed independent of $\mathcal{F}_T$.

In the optimal strategy (13), if $\nu = 0$ then we trade so as to move our position $y$ in the direction of decreasing $J$, with rate controlled by the coefficient $\eta$ of temporary impact. If $\nu > 0$, then we also take account of the effect of our permanent impact on the stock price, both directly via the term $\nu J_p$, and indirectly via the change in $\Delta$ by the term $\nu \Gamma J_y$.

The last term in (13), $\theta = \cdots + \nu y/2\eta$, expresses an arbitrage. Since our position is marked to market via the public price of the underlying, we increase the value of our holdings by trading so as to increase the price if we are long relative to the optimal hedge, and to decrease the price if we are short. This effect is intrinsic in our wealth specification (7), and will be controlled by risk aversion.

We will not solve the equation in full generality but will stick to two major sub-cases.

### 3.2 Constant Gamma approximation

The most illuminating case is the approximation that $\Gamma$ is constant, as at the end of Section 2.5. This considerably simplifies the problem by eliminating the dependence on the state variable $P_t$, and allows us to exhibit the essential features of local hedging without losing ourselves in complexities due to the global shape of the option price. The problem becomes essentially the well-known stochastic linear regulator with time dependence.

With this assumption, the option’s delta varies linearly with the stock price, as in (11), the terminal penalty is as in (12), and $\Gamma$ is constant in the state dynamics (8,9). Assumption (5) says that the constant value $G = 1 + \nu \Gamma > -1$.

Further, $J(t, p, y) = J(t, y)$ independent of $p$, since the terminal data does not depend on $p$ and the PDE (14) introduces no $p$-dependence. We look for a solution quadratic in the mishedge $y$

$$J(t, y) = \frac{1}{2} A_2(T-t) y^2 + A_0(T-t).$$

11
To solve (14), $A_0(\tau)$ and $A_2(\tau)$ must satisfy the ordinary differential equations

$$
\dot{A}_2 = 2\lambda \sigma^2 - \frac{1}{2\eta} (GA_2 - \nu)^2 \quad (17)
$$

$$
\dot{A}_0 = \frac{1}{2} \Gamma^2 \sigma^2 A_2. \quad (18)
$$

for $\tau \geq 0$, with

$$
A_2(0) = 2\lambda \Sigma^2 \quad \text{and} \quad A_0(0) = \lambda \Xi^2.
$$

To solve (17), note that the graph of the function of $A_2$ on the right is a parabola opening downwards, crossing $\dot{A}_2 = 0$ at the critical points

$$
A_2^\pm = \frac{1}{G} \left( \nu \pm 2\sqrt{\eta \lambda \sigma^2} \right). \quad (19)
$$

For an initial value $A_2(0) > A_2^-$, $A_2(\tau)$ moves monotonically towards the stable point $A_2^+$ as $\tau$ increases: it increases to $A_2^+$ if $A_2^- < A_2(0) < A_2^+$ and it decreases to $A_2^+$ if $A_2(0) > A_2^+$. If $A_2(0) < A_2^-$, then $A_2(\tau)$ explodes to $-\infty$ at a finite time $\tau > 0$.

We assume that the initial data is in the stable region: $2\lambda \Sigma^2 > A_2^-$ or

$$
\nu < 2\left( \sqrt{\eta \lambda \sigma^2} + G \lambda \Sigma^2 \right). \quad (20)
$$

This requires that either $\lambda \sigma^2$ or $\lambda \Sigma^2$ be sufficiently large compared to $\nu$. It is in this sense that risk aversion controls the potential arbitrage opportunity introduced by permanent impact and our mark to market formulation, as noted at the end of Section 3.1.

Under assumption (20), $A_2(\tau)$ and hence $A_0(\tau)$ exist for all $\tau \geq 0$, $A_2(\tau)$ is uniformly bounded, $A_0(\tau)$ grows linearly, and $J(t, y)$ exists for all $t \leq T$. Indeed,

$$
A_2(\tau) = \frac{1}{G} \left( \nu + 2\eta \kappa h(\kappa G \tau) \right) \quad (21)
$$

with the function $h(s)$ given by

$$
h(s) = \frac{1 - u}{1 + u}, \quad u = \frac{1 - h_0}{1 + h_0} e^{-2s}, \quad (22)
$$

(see Figure 3), and the constants

$$
h_0 = \frac{G \lambda \Sigma^2 - 2\nu}{\eta \kappa} \quad \text{and} \quad \kappa = \sqrt{\frac{\lambda \sigma^2}{\eta}}. \quad (23)
$$

Condition (20) assures us that $h_0 > -1$. Also, $h(s) \geq h_0$ for $h_0 \leq 1$, and hence $A_2(\tau) \geq 0$: the value function is convex in the mishedge. The optimal trading intensity (13) is

$$
\theta_t = -\kappa h(\kappa G(T - t)) Y_t. \quad (24)
$$

This depends only relatively weakly on the value of $\Gamma$, via the term $\nu \Gamma$ in $G = 1 + \nu \Gamma$.

**Theorem 1.** Under assumption (20), expression (24) is the optimal strategy. Under this strategy, $Y_T \neq 0$ almost surely and in fact, $\{ |Y_T| > R \} > 0$ for all $R > 0$. 

12
Figure 3: The control coefficient \( h(\tau) \). The horizontal axis is scaled time to close of trading \( s = \kappa G(T - t) \approx \kappa(T - t) \). The vertical axis is the coefficient \( h \) in the linear response \( \vartheta_t = -\kappa h Y_t \). When time to close is greater than \( 1/\kappa \), the coefficient is 1. As close approaches, the coefficient may increase, decrease, or even become negative, depending on the relative magnitudes of overnight risk and permanent impact.

**Proof.** The Martingale Principle of Optimal Control tells us that

\[
M_t = \lambda \sigma^2 \int_0^t Y_s^2 \, ds - \nu \int_0^t Y_s \vartheta_s \, ds + \eta \int_0^t \vartheta_s^2 \, ds + J(t, Y_t)
\]

is a submartingale for all \( \vartheta_t \) and a martingale under the optimal control. We have exhibited a smooth solution \( J \) to the HJB equation (14,15) and we see that \( M_t \) has non-negative drift for all \( \vartheta \) and is a local martingale for \( \vartheta \) given in (24). To show that \( M \) is a martingale, we need only show that \( \mathbb{E}[M] < \infty \) for all \( \vartheta \in \Theta \) where \([\cdot]\) denotes quadratic variation.

Since \( A_2(T - t) \) is uniformly bounded for \( t \in [0,T] \),

\[
\mathbb{E}[M]_T = \mathbb{E} \int_0^T |J'(t,Y_t)|^2 \, dt \leq C^2 \mathbb{E} \int_0^T |Y_t|^2 \, dt .
\]

Itô’s Lemma and (9) give us

\[
\mathbb{E}Y_t^2 = Y_0^2 + \mathbb{E} \left[ \int_0^t 2Y_s dY_s + d[Y]_s \right] = Y_0^2 + \mathbb{E} \int_0^t \left[ 2G \vartheta_s Y_s + \sigma^2 \Gamma^2 \right] \, ds \leq Y_0^2 + \mathbb{E} \int_0^t \left[ C|Y_s|^2 + \sigma^2 \Gamma^2 \right] \, ds
\]

for some \( C > 0 \) independent of \( t \in [0,T] \), since \( h \) is bounded. Gronwall’s Lemma yields \( \mathbb{E}[M]_T < \infty \) and (24) is the optimal policy.
The second part also follows from the fact that $Y_T$ is given by a linear SDE (9). Its solution has a density that is non-singular with respect to the Lebesgue measure on $\mathbb{R}$ since $h$ is bounded. That is, because of the market-impact costs, the position is not perfectly delta hedged, even at the terminal time and there is a chance (albeit small) that $Y_T$ is far away from 0.

The agent’s trading share target for shares $X_t$ is the Black-Scholes delta hedge $\Delta(t, P_t)$, which varies in time due to price motions caused both by volatility and by his own trading. He constantly trades towards this target but is prevented from holding the exact Black-Scholes delta hedge by the temporary impact stemming from limited liquidity. The trading intensity $\theta_t$ is proportional to the degree of mishedge $Y_t$ and the urgency parameter $\kappa$. There is a greater penalty to being mishedged with higher underlying volatility $\sigma$ and risk aversion $\lambda$ so these parameters increase urgency. Similarly, a more illiquid market (higher $\eta$) makes trading more costly, which decreases trading intensity.

Our $\kappa$ is the same as in Almgren and Chriss [2000] where it was an “urgency parameter” dictating the speed of liquidation as a fraction of the position size. The $a/\lambda$ in Proposition 5 of Gârleanu and Pedersen [2013] is equivalent to $\kappa h$ in our setup, that is, the higher $\kappa$, the faster the agent trades towards the Merton-optimal portfolio.

Far from expiration, where $\kappa(T - t) \gg 1$ (we suppose $G = 1 + v\Gamma \approx 1$), $h \equiv 1$ and the trade rule is $\theta_t = -\kappa Y_t$. Near expiration, the solution falls into two cases depending on the value of $h_0$, that is, depending on the relative values of terminal risk and market impact.

- If $h_0 > 1$, then overnight risk dominates permanent impact. The trade rate increases as expiration is approached. The trader is willing to pay more in temporary impact costs to reduce the overnight risk of an imperfectly hedged position.

- If $h_0 < 1$, then permanent impact dominates overnight risk. If $h_0 < 0$, then in fact near expiration the trader trades so as to increase the mishedge. This is the arbitrage possibility noted in Section 3.1. If $0 < h_0 < 1$, then permanent impact only partially controls the dynamics, and trade rate is reduced but not reversed.

If $[0, T]$ is the trading day, then the case $h_0 > 1$ is the most realistic. Options market-makers typically increase their hedging towards the close of trading to minimize overnight exposure. The trader may choose a lower $h_0$ as options expiry approaches, selecting $h_0 = 0$ on the day of options expiry. However, this strategy may be deemed too risky and the trader may choose $h_0 > 0$ even at expiry to avoid the risk of being mishedged.

3.3 Effect on the price process

What would be the effect on the publicly observable price process, as the result of hedging by large traders? We first observe that since options are bilateral contracts, each long position has a corresponding short position and conversely. If all position owners hedge their positions, and if all have roughly similar market impact, then there will be no net effect on the price. The only effect will be a net total positive cost from temporary impact, which may be interpreted as premia paid by the hedgers to liquidity suppliers in order to complete their trades.
Presumably at least some market participants are trading the options because they want the options exposure to hedge other risks in their portfolio. Let us identify *buy side* traders as options position holders who do not hedge. *Sell side* traders will be the Wall Street firms who have sold these contracts. The sell side traders have no interest in owning the options exposure and hence will hedge their positions.

We therefore take $\Gamma$ to be the total exposure of all the sell side traders, that is, of all options position holders who hedge their options exposure. This $\Gamma$ may be positive or negative depending on whether the “street” is a net buyer or seller. It is not necessarily related to the option open interest. But conversations with market participants indicate that most professional traders are generally aware of the net positions of their counterparts across the industry.

Note that the example shown in Figure 1 shows something slightly different. There, the price dynamics is caused by a *single* large position holder who uses strongly suboptimal hedging techniques. Here we consider a population of hedgers who use optimal hedge strategies as outlined in this paper, and we determine the unavoidable effects that they would have on the market dynamics.

As above, we assume that $\Gamma$ can be taken constant during the period of interest. We also assume for simplicity that we are far enough from expiration so $\kappa(T - t) \gg 1$ and hence $h = 1$ so that the hedge strategy is $\theta_t = -\kappa Y_t$. Then (9) gives

$$Y_t = \sigma \Gamma \int_0^t e^{-\tilde{\kappa}(t-s)} dW_s.$$

We assume that the position is initially correctly hedged so $Y_0 = 0$. We denote

$$\tilde{\kappa} = G \kappa$$

with $\tilde{\kappa} \approx \kappa$ if permanent impact $\nu$ is not too large (recall $G = 1 + \nu \Gamma$).

The approximate instantaneous size of the mishedge $Y_t$ is

$$\mathbb{E} Y_t^2 = \frac{\sigma^2 \Gamma^2}{2 \tilde{\kappa}} = \frac{\sigma^2 \Gamma^2}{2G \sqrt{\eta} \sqrt{\lambda}}.$$  

The mishedge size, measured in shares (recall that $Y = X - \Delta$) increases in proportion to the total position size $\Gamma$ as expected, except for feedback effects contained in the factor $G = 1 + \nu \Gamma$. For a given position size, the mishedge increases as risk aversion $\lambda$ decreases, and it decreases as temporary impact $\eta$ decreases. Permanent impact $\nu$ does not appear in this expression at leading order, except as a small adjustment of the value to which hedging is made.

The total amount lost by the hedgers to temporary market impact is approximately

$$\int_0^T 2\eta \theta_t^2 \, dt = \int_0^T 2\eta \kappa^2 Y_t^2 \, dt \sim 2T \sigma^3 \Gamma^2 \lambda^{1/2} \eta^{1/2}.$$  

As temporary impact $\eta \to 0$, not only does the optimal hedge position track the Black-Scholes value more and more closely, but also the total cost of this hedge decreases to zero, even though trading becomes more and more active. We eliminate the plausible but false scenario in which the hedge error decreases to zero but the trading cost increases. In the limit of zero temporary cost we fully recover the Black-Scholes solution.
To determine the price process, note that \( \Delta(t, P_t) = \Delta_0 - \Gamma(P_t - P_0) \), we have
\[
Y_t = X_t - \Delta(t, P_t) = X_t - X_0 + \Gamma(P_t - P_0).
\]
Solving for \( P_t - P_0 \) between this and (1), we obtain
\[
G(P_t - P_0) = \nu Y_t + \sigma W_t
\]
or
\[
P_t = P_0 + \frac{\sigma}{G} \left( W_t + \nu \Gamma \int_0^t e^{-\tilde{k}(t-s)} \, dW_s \right).
\]

The price process given by (26) has momentum or mean reversion across time scales of length \( \sim \kappa^{-1} \), depending on the sign of \( \Gamma \). One way to describe such a process is to compute the effective variance \( \sigma_{\text{eff}}^2(\delta t) \) that would be measured on a time interval of fixed length \( \delta t \). In the market microstructure literature, this is often called the “signature” of the process, though it is usually taken to reflect effects such as bid-ask bounce rather than the impact effects considered here. In this case we obtain
\[
\sigma_{\text{eff}}^2(\delta t) = \frac{1}{\delta t} \mathbb{E}(P_{t+\delta t} - P_t)^2 = \left( \frac{\sigma}{G} \right)^2 \left( 1 + (2 + \nu \Gamma) \nu \Gamma \frac{1 - e^{-\tilde{k}\delta t}}{\tilde{k}\delta t} \right).
\]

We readily see that
\[
\sigma_{\text{eff}}(\delta t) \sim \begin{cases} 
\sigma & \text{for } \tilde{k} \delta t \ll 1, \text{ and} \\
\frac{\sigma}{G} & \text{for } \tilde{k} \delta t \gg 1.
\end{cases}
\]

While the instantaneous price process has the original volatility \( \sigma \), a modified volatility will be observed on time scales longer than the hedge time scale. If \( \Gamma > 0 \), then this modified volatility will be smaller than the original volatility; as observed at the end of Section 2.2, the long \( \Gamma \) position is easy to hedge since trading towards the hedge portfolio moves the price in, reducing effective volatility. This is related to the “pinning” near expiration modeled by Avellaneda and Lipkin [2003], when market makers are net long. If \( \Gamma < 0 \) then volatility is enhanced, since hedge trading pushes the price away.

Temporary impact \( \eta \) sets the shortest time scale on which this modified volatility can be observed, but its magnitude is determined entirely by the permanent impact \( \nu \) and the net position \( \Gamma \) of the hedgers. Thus Lions and Lasry [2006, 2007], with no temporary impact, obtained a modified Brownian motion on infinitesimal time scales.

In principle this effect could be observed from market data, if a reliable estimate for the total hedge position \( \Gamma \) were available.

### 3.4 No permanent impact, general Gamma

We can relax the constant gamma assumption and allow for general options. However, to make the solution tractable, we need to dispense with permanent impact \( (\nu = 0) \). We are still able to obtain a fairly explicit solution for the control \( \theta_t \), which illustrates an asymmetry near the close of trading.
Theorem 2. The optimal control is (compare (24))

$$ \theta_t = -\kappa h(\kappa(T-t))(Y_t - \bar{Y}_t), $$  \quad (29)

with

$$ \bar{Y}(t, P_t) = \frac{\lambda}{\eta \kappa \sinh \kappa(T-t) + \lambda \Sigma^2 \cosh \kappa(T-t)} F(T-t, P_t). $$  \quad (30)

Here $F : \mathbb{R}^+ \times \mathbb{R} \rightarrow \mathbb{R}$ is the solution of the heat equation $\dot{F} = \frac{1}{2} \sigma^2 F''$ with initial data

$$ F(0, p) = \mathbb{E}\left[ \Pi | P_T = p \right]. $$

Proof. We look for a solution to (14) in the form

$$ J(t, p, y) = \frac{1}{2} A_2(T-t) y^2 + A_1(T-t, p) y + A_0(T-t, p), $$  \quad (31)

from which we obtain the system of one ordinary and two partial differential equations

$$ \begin{align*}
\dot{A}_2 &= 2\lambda \sigma^2 - \frac{1}{2\eta} A_2^2 \\
\dot{A}_1 &= \frac{1}{2} \sigma^2 A_1' - \frac{1}{2\eta} A_2 A_1 \\
\dot{A}_0 &= \frac{1}{2} \sigma^2 A_0' + \sigma^2 \Gamma A_1' + \frac{1}{2} \sigma^2 \Gamma^2 A_2 - \frac{1}{4\eta} A_1^2
\end{align*} $$

with $A_2(0) = 2\lambda \Sigma^2$. (If $\nu \neq 0$ and $\Gamma$ is not constant, then terms with $\nu \Gamma$ in $\dot{A}_2$ force $A_2$ to depend on $p$ and make the problem intractable.) Here $\Gamma = \Gamma(t, p)$ is a function of arbitrary form, satisfying (4) and (5).

The solution for $A_2$ is the same as in (21) with $\nu = 0$:

$$ A_2(\tau) = 2\eta \kappa h(\kappa \tau) $$

with $h_0 = \lambda \Sigma^2 / \eta \kappa$. This $h_0$ is nonnegative and positive if overnight risk is nonzero. Hence $A_2(\tau)$ is nonnegative, strictly positive except possibly at $\tau = 0$, and bounded.

To solve for $A_1(\tau, p)$, write

$$ A_1(\tau, p) = \exp\left(-\frac{1}{2\eta} \int_0^\tau A_2(s) \, ds\right) B(\tau, p) $$

so that $\dot{B} = \frac{1}{2} \sigma^2 B''$ and $B(0, p) = A_1(0, p) = -2\lambda F(0, p)$. Hence $B(\tau, p) = -2\lambda F(\tau, p)$, where $F$ is defined as the solution to this heat equation. From (13), the optimal control is

$$ \theta_t = -\frac{1}{2\eta} J_y = -\frac{1}{2\eta} (A_2 Y_t + A_1) = -\frac{1}{2\eta} A_2 (Y_t - \bar{Y}), \quad \bar{Y} = -\frac{A_1}{A_2} $$

Substituting the expressions for $A_1$, $A_2$, and $h$, and carrying out the integration, gives the claimed result.

The verification argument proceeds similarly to the constant-$\Gamma$ case. \hfill \square
The optimal strategy (29) says that we trade not towards the perfect Black-Scholes hedge \( Y_t = 0 \) as for the constant-\( \Gamma \) case, but towards an offset value \( \overline{Y} \). It is evident from (30) that \( \overline{Y}_t \to 0 \) as \( \kappa(T - t) \to \infty \), since \( F(\tau, P_t) \) obeys the maximum principle, and the sinh and cosh in the denominator tend to \( \infty \). The offset is negligible when we are more than one typical hedge time away from the close of trading. The offset is also zero if the overnight risk is such that \( F(0, p) = 0 \). The asymmetry is thus due entirely to overnight hedging.

It may be surprising that the asymmetry in the option value does not appear before we are near to the close of trading. An explanation for this is that the hedge strategy is given in terms of the change in \( \Delta \) rather than in terms of the underlying price change. Thus a positive price change \( \delta P \) and its opposite \( -\delta P \) may cause changes of different size in the mishedge \( Y_t \), which will cause trading at different rates.

To understand the nature of this terminal asymmetry, we note that for \( \xi \) and \( \Pi \) evaluated from an overnight process (rather than the more general formulation mentioned in Section 2.5), by Itô’s Isometry

\[
F(0, p) = \sigma^2 \mathbb{E} \left[ \int_0^{T^*} (\Delta(t, P_t) - \Delta(T, P_T)) \, dt \mid P_T = p \right].
\]

Since the price process has zero drift, this quantity is zero if \( \Gamma \) is constant and \( \Delta' = 0 \).

If \( \Gamma \) is increasing in \( p \) near \( P_T \), then \( \Delta'' < 0 \), \( \Delta(t, P) \) is concave down in \( p \), and \( F(0, p) < 0 \); also, \( F(T - t, P_t) < 0 \) for \( t \) near \( T \) and \( P_t \) near \( P_T \). Thus \( \overline{Y}_t < 0 \) and we trade towards a state with \( X_t < \Delta(t, P_t) \). We desire to end the day “underhedged,” because during the unhedgeable overnight moves, the expected decrease in optimal hedge if \( P_t \) decreases is smaller than the expected increase if \( P_t \) increases. The situation is the reverse if \( \Gamma \) is increasing in \( p \).

Although this asymmetry appears explicitly only near the close of trading, in the middle of the trading day, the asymmetry appears implicitly via the definition of the mishedge \( Y_t = X_t - \Delta(t, P_t) \). If the price changes by a small amount \( \delta P_t \), then the change in the value of \( \Delta \) may be larger for changes in one direction than in the other. Thus the change in \( Y_t \) will be larger on one side, and the rate of trading will be larger on that side. The target portfolio is always the perfect hedge, unless near close when we are facing an unhedgeable asymmetric risk.

## 3.5 Discrete time

The example in the Introduction has illustrated the risks of using a naive hedging strategy on a discrete time grid. We now show how to do a more correct computation of the hedge strategy with discrete time steps.

Suppose that we are allowed to reevaluate our trade strategy only at a discrete set of times \( t_0, \ldots, t_{N-1} \), with \( t_0 = 0 \) and \( t_N = T \). We do not assume that these times are uniformly spaced, or that the time intervals \( \delta_k = t_{k+1} - t_k \) are small. At each time \( t_k \) for \( k = 0, \ldots, N - 1 \), we set our trade rate \( \theta_k \), which is to be held constant through the entire interval \( t_k \leq t < t_{k+1} \). We denote by \( \theta_k, P_k, \) etc. the values at \( t = t_k \).

For simplicity, we use the constant-\( \Gamma \) approximation of Section 3.2. Then the share holdings, the stock price, and the mishedge evolve for \( t \) between \( t_k \) and \( t_{k+1} \) according
to (compare (8,9))
\[
\begin{align*}
\theta_t &= \theta_k, \\
P_t &= P_k + \nu \theta_k(t - t_k) + \sigma(W_t - W_k), \text{ and} \\
Y_t &= Y_k + G \theta_k(t - t_k) + \sigma \Gamma(W_t - W_k),
\end{align*}
\]
in which we again abbreviate \(G = 1 + \nu \Gamma\).

The obvious strategy would evaluate the continuous-time rule (24) at \((t_k, Y_k)\):
\[
\theta_k = -\kappa h Y_k
\]
where \(h\) is evaluated at \(\kappa G(T - t_k)\). But under this rule,
\[
Y_{k+1} = (1 - G h \kappa \delta) Y_k
\]
(we denote \(\delta = \delta_k\) for brevity). This gives the well-known Euler instability, with exponential growth in \(|Y_k|\), unless \(\kappa \delta < 2\) so that \(|1 - G h \kappa \delta| < 1\) (recall that \(G\) and \(h\) have values near one). For small temporary impact \(\eta\), the relaxation rate \(\kappa\) may be large, and this is a very severe restriction on the maximum time step \(\delta\). We need a time discretization that does not depend on the value of \(\kappa \delta\).

To compute the fully optimal discrete-time solution, we compute
\[
J(t_k, y) = \inf_{\theta_k, \ldots, \theta_{n-1}} \mathbb{E} \left[ \lambda \left( Y_T \Pi - \xi \right)^2 + \sum_{j=k}^{N-1} \int_{t_j}^{t_{j+1}} \left( \lambda \sigma \theta^2 - \nu Y_t \theta_t + \eta \theta_t^2 \right) dt \middle| Y_k = y \right]
\]
\[
= \inf_{\theta} \mathbb{E} \left[ \int_{t_k}^{t_{k+1}} \left( \lambda \sigma \theta^2 - \nu Y_t \theta_t + \eta \theta_t^2 \right) dt + J(t_{k+1}, Y_{k+1}) \middle| Y_k = y, \theta_k = \theta \right]
\]
\[
= \inf_{\theta} \left[ \lambda \sigma \left( y^2 + \frac{1}{2} \sigma^2 \Gamma^2 + G \theta y \right) \delta + \frac{1}{3} G^2 \theta^2 \delta^2 \right] - \nu \theta \left[ y + \frac{1}{2} G \theta \delta \right] + \mathbb{E} \left[ J(t_{k+1}, Y_{k+1}) \middle| Y_k = y, \theta_k = \theta \right].
\]

We look for a solution in the form
\[
J(t_k, y) = \frac{1}{2} A_k y^2 + C_k \quad \text{for } k = 0, \ldots, N,
\]
which gives
\[
\frac{1}{2} A_k y^2 + C_k = \inf_{\theta} \left[ \lambda \sigma \left( y^2 + \frac{1}{2} \sigma^2 \Gamma^2 + G \theta y \right) \delta + \frac{1}{3} G^2 \theta^2 \delta^2 \right] - \nu \theta \left[ y + \frac{1}{2} G \theta \delta \right] + \mathbb{E} \left[ J(t_{k+1}, Y_{k+1}) \middle| Y_k = y, \theta_k = \theta \right] + \frac{1}{2} A_{k+1} \left( y^2 + \left( \sigma^2 \Gamma^2 + 2 G \theta y \right) \delta + G^2 \theta^2 \delta^2 \right) + C_{k+1}.
\]
The optimal control is
\[
\theta_k = -\frac{GA_{k+1} - \nu + \lambda \sigma^2 G\delta}{2\eta + (GA_{k+1} - \nu)G\delta + \frac{2}{3}\lambda \sigma^2 (G\delta)^2} Y_k,
\] (32)
and we obtain the iterative relation \(A_N = 2\lambda \Sigma^2\) and \(A_k = F(A_{k+1})\), with
\[
F(A) = A + \left(2\lambda \sigma^2 - \frac{(GA - \nu + \lambda \sigma^2 G\delta)^2}{2\eta + (GA - \nu)G\delta + \frac{2}{3}\lambda \sigma^2 (G\delta)^2}\right) \delta.\] (33)

In the limit \(\delta \to 0\), (32) reproduces (13), and (33) reproduces (17).

**Theorem 3.** Under the same stability condition (20) on the parameters as for the continuous-time case, and for arbitrary time steps \(\delta_k\), the dynamics given by (33) gives a well-behaved evolution for \(A_k\), with \(A_k \geq 0\) for each \(k\). “Well-behaved” means that if \(\delta_k\) is constant, then \(A_k\) tends monotonically to a fixed value as \(k\) decreases, and if \(\delta_k\) varies, then \(A_k\) moves always in the direction of a variable target.

**Proof.** \(F(A) - A\) is rational in \(A\). Its numerator is quadratic in \(A\) with zeros at
\[
A_{\pm}(\delta) = \frac{1}{G} \left(\nu \pm \sqrt{4\eta \lambda \sigma^2 + \frac{1}{3} \lambda \sigma^2 (G\delta)^2}\right)
\]
which approach the stable points (19) for the differential equation as \(\delta \to 0\). The numerator is positive for \(A_-(\delta) < A < A_+(\delta)\) and negative for \(A > A_+(\delta)\). Since \(A_-(\delta) < A_-(0)\) for \(\delta > 0\), we may say that the numerator is positive for \(A_-(0) < A < A_+(\delta)\).

The denominator of \(F(A) - A\) is linear in \(A\), with a single zero at
\[
\tilde{A}_0(\delta) = \frac{1}{G} \left(\nu - \frac{2\eta}{G\delta} - \frac{2}{3} \lambda \sigma^2 G\delta\right).
\]
The denominator is positive for \(A > \tilde{A}_0(\delta)\). Maximising \(\tilde{A}_0(\delta)\) over \(\delta\), we can say that the denominator is positive for \(A > \tilde{A}_0^{\text{max}}\) for all \(\delta\), with
\[
\tilde{A}_0^{\text{max}} = \max_\delta \tilde{A}_0(\delta) = \frac{1}{G} \left(\nu - \frac{4}{\sqrt{3}} \sqrt{\eta \lambda \sigma^2}\right) < A_-(0).
\]
In particular, the denominator is positive for \(A > A_-(0)\).

Thus \(F(A) - A > 0\) for \(A_-(0) < A < A_+(\delta)\) and \(F(A) - A < 0\) for \(A > A_+(\delta)\). Condition (20) assures us that \(A_N > A_-(0)\), and hence that \(A_k > A_-(0)\) for all \(k \leq N\).

Furthermore,
\[
F'(A) = \frac{\left(2\eta - \frac{1}{3} \lambda \sigma^2 (G\delta)^2\right)^2}{\left(2\eta + (GA - \nu)G\delta + \frac{2}{3} \lambda \sigma^2 (G\delta)^2\right)^2}
\]
which is always nonnegative, and strictly positive except at a special value of \(\delta\) such that \(\eta = \frac{1}{3} \lambda \sigma^2 (G\delta)^2\), that is, \(\kappa^2 \delta^2 = 6/G^2\). At that special value, \(F'(A)\) is zero and indeed \(F(A)\) has the constant value \(A_+(\delta)\). Positivity of the derivative assures us that \(F(A) \leq A_+(\delta)\) for \(A_-(0) < A < A_+(\delta)\), and \(A_+(\delta) \leq F(A)\) for \(A \geq A_+(\delta)\).
Combining the two results above, we have $A < F(A) \leq A_+(\delta)$ for $A - (0) \leq A < A_+(\delta)$, and $A_+(\delta) \leq F(A) < A$ for $A \geq A_+(\delta)$, and this gives us convergence to the stable point $A_+(\delta)$. If the time step $\delta$ varies from step to step, then the dynamics will track the moving stationary point.

For the positivity, the above give $F(A) \geq \min\{A, A_+(\delta)\}$. We have $A_N = 2\lambda\Sigma^2 \geq 0$; also $A_+(\delta) \geq 0$. Hence $A_k \geq 0$ for all $k \leq N$. That is, the value function is convex and the stationary point is indeed a minimum.

4 Conclusion

We have considered the problem of hedging an options position in the presence of both temporary and permanent impact. The solution consists of smooth trading in the direction of a target portfolio determined by the Black-Scholes delta-hedge, at a rate determined by the balance between temporary market impact and risk aversion. Permanent market impact causes a modification of the realised volatility in the public market, on time scales longer than the intrinsic hedge time.

This provides a way to think about market impact for options trading. Suppose that a buy-side trader purchases a large quantity of options from a sell-side trader. We assume that the buy-side trader the trader purchases the option to hedge an external risk, and so does not hedge the position. The sell-side trader has no outside risk, and so hedges the option position. The market impact of this trade will be felt in two ways. First, the implied volatility of the option contract will rise, as the sell-side dealer raises his prices to counteract the buy-side demand. Second, the realised volatility of the underlying asset will also rise, as the sell-side dealer hedges his position in the open market. That is, in (28), we have $\Gamma < 0$ since the hedger is short the option; thus $G = 1 + \nu\Gamma < 1$, and $\sigma_{\text{eff}} > \sigma$. Liquidity-demanding trading in an options contract thus affects both types of volatility.

We make predictions that can be tested, if suitable market data can be found. The key variable is $\Gamma$ which, as discussed in Section 3.3, represents the entire net position of traders who are hedging their options position rather than holding the option to hedge exogeneous sources of risk. We typically assume these market participants to be sell-side dealers as well as market makers. This quantity is not related to total open interest in the option, but requires more detailed information about what types of market participants hold what net postions. This would be similar to the Liquidity Data Bank data for futures (see, for example, Almgren and Burghardt [2011]) previously available from the Chicago Mercantile Exchange. If similar data could be obtained for options (on any asset class) then the prediction of a relationship between net position of hedgers, realised volatility, and time to expiration could be tested.
