Random Walks in Random Environments

Ofer Zeitouni *

Abstract

Random walks in random environments (RWRE's) have been a source of surprising phenomena and challenging problems since they began to be studied in the 70's. Hitting times and, more recently, certain regeneration structures, have played a major role in our understanding of RWRE's. We review these and provide some hints on current research directions and challenges.

2000 Mathematics Subject Classification: 60K37, 82C44.
Keywords and Phrases: Random walks, Random environment, Regeneration.

1. Introduction

Let $S$ denote the 2d-dimensional simplex, set $\Omega = S^{\mathbb{Z}^d}$, and let $\omega(z, \cdot) = \{\omega(z, z + \epsilon)\}_{\epsilon \in \mathbb{Z}^d, |\epsilon|=1}$ denote the coordinate of $\omega \in \Omega$ corresponding to $z \in \mathbb{Z}^d$. $\Omega$ is an “environment” for an inhomogeneous nearest neighbor random walk (RWRE) started at $x$ with quenched transition probabilities $P_\omega(x_{n+1} = x + \epsilon | X_n = x) = \omega(x, x + \epsilon) (\epsilon \in \mathbb{Z}^d, |\epsilon|=1)$, whose law is denoted $P_\omega^n$. In the RWRE model, the environment is random, of law $P$, which is always assumed stationary and ergodic. We also assume here that the environment is elliptic, that is there exists an $\epsilon > 0$ such that $P$-a.s., $\omega(x, x + \epsilon) \geq \epsilon$ for all $x, \epsilon \in \mathbb{Z}^d, |\epsilon|=1$. Finally, we denote by $P$ the annealed law of the RWRE started at 0, that is the law of $\{X_n\}$ under the measure $P \times P_\omega^0$.

When $d = 1$, we write $\omega_x = \omega(x, x + 1)$, $\rho_x = \omega_x/(1 - \omega_x)$, and $u = E_P \log \rho_0$. The following theorem reveals the surprising phenomena associated with the RWRE:

Theorem 1.1 (Transience, recurrence, limit speed) (a) With $\text{sign}(0) = 1$, it holds that $P$-a.s.,

$$\limsup_{n \to \infty} \kappa X_n = \text{sign}(\kappa u) \infty, \quad \kappa = \pm 1.$$

E-mail: zeitouni@ee.technion.ac.il
Further, there is a $v$ such that
\[ \lim_{n \to \infty} \frac{X_n}{n} = v, \quad \mathbb{P} - \text{a.s.,} \quad (1.2) \]

$v > 0$ if $\sum_{i=1}^{\infty} E_P(\prod_{j=0}^{i} \rho_{-j}) < \infty$, $v < 0$ if $\sum_{i=1}^{\infty} E_P(\prod_{j=0}^{i} \rho_{-j}^{-1}) < \infty$, and $v = 0$ if both these conditions do not hold.

(b) If $P$ is a product measure then
\[
v = \begin{cases} 
\frac{1 - E_P(\rho_0)}{1 + E_P(\rho_0^{-1})}, & E_P(\rho_0) < 1 \\
\frac{1 - E_P(\rho_0^{-1})}{1 + E_P(\rho_0^{-1})}, & E_P(\rho_0^{-1}) < 1 \\
0, & \text{else}. 
\end{cases} \quad (1.3)
\]

Theorem 1.1 is essentially due to [25]; see [29] for a proof in the general ergodic setup. The surprising features of the RWRE model alluded to above can be appreciated if one notes, already for a product measure $P$, that the RWRE can be transient with zero speed $v$. Further, if $P$ is a product measure and $v_0(\omega)$ denotes the speed of a (biased) simple random walk with probability of jump to the right equal, at any site, to $\omega_0$, then Jensen’s inequality reveals that $|v| \leq |E_P(v_0(\omega))|$, with examples of strict inequality readily available.

The reason for this behavior is that the RWRE spends a large time in small traps. This is very well understood in the case $d = 1$, to which the next section is devoted. We introduce there certain hitting times, show how they yield precise information on the RWRE, and describe the analysis of these hitting times. Understanding the behavior of the RWRE when $d > 1$ is a major challenging problem, on which much progress has been done in recent years, but for which many embarrassing open questions remain. We give a glimpse of what is involved in Section 3., where we introduce certain regeneration times, and show their usefulness in a variety of situations. Here is a particularly simple setup where law of large numbers (and CLT’s, although we do not emphasize that here) are available:

**Theorem 1.4** Assume $P$ is a product measure, $d \geq 6$, and $\omega(x, x + e) = \eta > 0$ for $e = \pm e_i, i = 1, \ldots, 5$. Then there exists a deterministic constant $v$ such that $X_n/n \to v$, $\mathbb{P}$-a.s..

### 2. The one-dimensional case

**Recursions**

Let us begin with a sketch of the proof of Theorem 1.1. The transience and recurrence criterion is proved by noting that conditioned on the environment $\omega$, the Markov chain $X_n$ is reversible. More explicitly, fix an interval $[m_-, m_+]$ encircling the origin and for $z$ in that interval, define
\[
\mathcal{V}_{m_-, m_+}(z) := P_\omega^z(\{X_n\} \text{ hits } m_- \text{ before hitting } m_+). 
\]
Then,
\[
\gamma_{m_-,m_+}(z) = \frac{\sum_{i=z+1}^{m_+} \prod_{j=z+1}^{i-1} \rho_j}{\sum_{i=z+1}^{m_+} \prod_{j=z+1}^{i-1} \rho_j + \sum_{i=-m_-+1}^{z} \left( \prod_{j=i}^{z} \rho_j^{-1} \right)},
\]
(2.1)
from which the conclusion follows. The proof of the LLN is more instructive: define the hitting times \( T_n = \min \{ t > 0 : X_t = T_n \} \), and set \( \tau_i = T_{i+1} - T_i \). Suppose that \( \limsup_{n \to \infty} X_n/n = \infty \). One checks that \( \tau_i \) is an ergodic sequence, hence \( T_n/n \to E(\tau_0) \) \( \mathbb{P} \)-a.s., which in turns implies that \( X_n/n \to 1/E(\tau_0) \), \( \mathbb{P} \)-a.s. But,
\[
\tau_0 = 1 \{ X_1 = 1 \} + 1 \{ X_1 = -1 \} (1 + \tau_{-1}^{-} + \tau_{0}^{-}),
\]
where \( \tau_{-1}^{-} \) \( (\tau_{0}^{-}) \) denote the first hitting time of 0 (1) for the random walk \( X_n \) after it hits \(-1\). Hence, taking \( P^\omega \) expectations, and noting that \( \{ E_{P^\omega}(\tau_i) \}_i \) are, \( P \)-a.s., either all finite or all infinite,
\[
E_{P^\omega}(\tau_0) = \frac{1}{\omega_0} + \rho_0 E_{P^\omega}(\tau_{-1}^{-}),
\]
(2.2)
When \( P \) is a product measure, \( \rho_0 \) and \( E_{P^\omega}(\tau_{-1}^{-}) \) are \( P \)-independent, and taking expectations results with \( E(\tau_0) = (1 + E_P(\rho_0))/(1 - E_P(\rho_0)) \) if the right hand side is positive and \( \infty \) otherwise, from which (1.3) follows. The ergodic case is obtained by iterating the relation (2.2).

The hitting times \( T_n \) are also the beginning of the study of limit laws for \( X_n \). To appreciate this in the case of product measures \( P \) with \( E_P(\log \rho_0) < 0 \) (i.e., when the RWRE is transient to \(+\infty\)), one first observes that from the above recursions,
\[
E(\tau_0^{-}) < \infty \iff E_P(\rho_0^{-}) < 1.
\]
Defining \( s = \max \{ r : E_P(\rho_0^r) < 1 \} \), one then expects that \( (X_n - v_n) \), suitably rescaled, possesses a limit law, with \( s \)-dependent scaling. This is indeed the case: for \( s > 2 \), it is not hard to check that one obtains a central limit theorem with scaling \( \sqrt{t} \) (this holds true in fact for ergodic environments under appropriate mixing assumptions and with a suitable definition of the parameter \( s \), see [29]). For \( s \in (0,1) \cup (1,2) \), one obtains in the i.i.d. environment case a Stable(\( s \)) limit law with scaling \( t^{1/s} \) (the cases \( s = 1 \) or \( s = 2 \) can also be handled but involve logarithmic factors in the scaling and the deterministic shift). In particular, for \( s < 2 \) the walk is sub-diffusive. We omit the details, referring to [16] for the proof, except to say that the extension to ergodic environments of many of these results has recently been carried out, see [23].

Traps
The unusual behavior of one dimensional RWRE is due to the existence of traps in the medium. This is exhibited most dramatically when one tries to evaluate the probability of slowdown of the RWRE. Assume that \( P \) is a product measure, \( X_n \) is transient to \(+\infty\) with positive speed \( v \) (this means that \( s > 1 \) by Theorem 1.1), and that \( s < \infty \) (which means that \( P(\omega_0 < 1/2) > 0 \)). One then has:
Theorem 2.3 ([8, 11]) For any \( w \in [0, v] \), \( \eta > 0 \), and \( \delta > 0 \) small enough,

\[
\lim_{n \to \infty} \frac{\log P \left( \frac{\Delta_n}{n} \in (w - \delta, w + \delta) \right)}{\log n} = 1 - s, \tag{2.4}
\]

\[
\liminf_{n \to \infty} \frac{1}{n^{1-1/s+\eta}} \log P^0 \left( \frac{X_n}{n} \in (w - \delta, w + \delta) \right) = 0, \quad P - a.s. \tag{2.5}
\]

and

\[
\limsup_{n \to \infty} \frac{1}{n^{1-1/s-\eta}} \log P^0 \left( \frac{X_n}{n} \in (w - \delta, w + \delta) \right) = -\infty, \quad P - a.s.. \tag{2.6}
\]

(Extensions of Theorem 2.3 to the mixing environment setup are presented in [29]. There are also precise asymptotics available in the case \( s = \infty \) and \( P(\omega_0 = 1/2) > 0 \), see [20, 21]).

One immediately notes the difference in scaling between the annealed and quenched slowdown estimates in Theorem 2.3. These are due to the fact that, under the quenched measure, traps are given, whereas under the annealed measure \( \mathbb{P} \) one can create, at some cost in probability, larger traps.

To demonstrate the role of traps in the RWRE model, let us exhibit, for \( w = 0 \), a lower bound that captures the correct behavior in the annealed setup, and that forms the basis for the proof of the more general statement. Indeed, \( \{X_n \leq \delta \} \subset \{T_n \geq n\} \). Fixing \( R_k = R_k(\omega) := k^{-1} \sum_{i=1}^k \log \rho_i \), it holds that \( R_k \) satisfies a large deviation principle with rate function \( J(y) = \sup_{\lambda} (\lambda y - \log E_P(\rho_i^\lambda)) \), and it is not hard to check that \( s = \min_{y \geq 0} y^{-1} J(y) \). Fixing a \( y \) such that \( J(y)/y \leq s + \eta \), and \( k = \log n/y \), one checks that the probability that there exists in \([0, \delta n]\) a point \( z \) with \( R_k \circ \theta^z \omega \geq y \) is at least \( n^{1-s-\eta} \). But, the probability that the RWRE does not cross such a segment by time \( n \) is, due to (2.1), bounded away from 0 uniformly in \( n \). This yields the claimed lower bound in the annealed case. In the quenched case, one has to work with traps of size almost \( k = \log n/sy \) for which \( kR_k \geq y \), which occur with probability 1 eventually, and use (2.1) to compute the probability of an atypical slowdown inside such a trap. The fluctuations in the length of these typical traps is the reason why the slowdown probability is believed, for \( P.a.e. \omega \), to fluctuate with \( n \), in the sense that

\[
\liminf_{n \to \infty} \frac{1}{n^{1-1/s}} \log P^0_\omega \left( \frac{X_n}{n} \in (-\delta, \delta) \right) = -\infty, \quad P - a.s.,
\]

while it is known that

\[
\limsup_{n \to \infty} \frac{1}{n^{1-1/s}} \log P^0_\omega \left( \frac{X_n}{n} \in (-\delta, \delta) \right) = 0, \quad P - a.s..
\]

This has been demonstrated rigorously in some particular cases, see [10].

The role of traps, and the difference they produce between the quenched and annealed regimes, is dramatic in the scale of large deviations. Roughly, the exponential (in \( n \)) rate of decay of the probability of atypical events differ between the quenched and annealed regime:
**Theorem 2.7** The random variables $X_n/n$ satisfy, for P-a.e. realization of the environment $\omega$, a large deviations principle (LDP) under $P^\omega_0$ with a deterministic rate function $I_P(\cdot)$. Under the annealed measure $\mathbb{P}$, they satisfy a LDP with rate function

$$I(w) = \inf_{Q \in \mathcal{M}_\Omega} \left( h(Q|P) + I_Q(w) \right),$$

(2.8)

where $h(Q|P)$ is the specific entropy of $Q$ with respect to $P$ and $\mathcal{M}_\Omega$ denotes the space of stationary ergodic measures on $\Omega$.

Theorem 2.7 means that to create an annealed large deviation, one may first “modify” the environment (at a certain exponential cost) and then apply the quenched LDP in the new environment. We refer to [13] (quenched) and [3, 7] for proofs and generalizations to non i.i.d. environments.

**Sinai’s recurrent walk and aging**

When $E_P(\log \rho_0) = 0$, traps stop being local, and the whole environment becomes a diffused trap. The walk spends most of its time “at the bottom of the trap”, and as time evolves it is harder and harder for the RWRE to move. This is the phenomenon of aging, captured in the following theorem:

**Theorem 2.9** There exists a random variable $B^n$, depending on the environment only, such that

$$\mathbb{P} \left( \left| \frac{X_n}{(\log n)^2} - B^n \right| > \eta \right) \to 0.$$  

Further, for $h > 1$,

$$\lim_{\eta \to 0} \lim_{n \to \infty} \mathbb{P} \left( \left| \frac{X_n - X_n}{(\log n)^2} \right| < \eta \right) = \frac{1}{h^2} \left[ \frac{2}{3} - \frac{2}{3} e^{-(h-1)} \right].$$

(2.10)

The first part of Theorem 2.9 is due to Sinai [24], with Kesten [15] providing the evaluation of the limiting law of $B^n$. The second part is implicit in [12], we refer to [5] and [29] for the proof and references.

### 3. Multi-dimensional RWRE

**Homogenization**

Two special features simplify the analysis of the RWRE in the one-dimensional case: first, for every realization of the environment, the RWRE is a reversible Markov chain. This gave transience and recurrence criteria. Then, the location of the walk at the hitting times $T_n$ is deterministic, leading to stationarity and mixing properties of the sequence $\{\tau_n\}$ and to a relatively simple analysis of their tail properties. Both these features are lost for $d > 1$.

A (by now standard) approach to homogenization problems is to consider the environment viewed from the particle. More precisely, with $\theta^x$ denoting the $\mathbb{Z}^d$ shift by $x$, the process $\omega_n = \theta^{x_n} \omega$ is a Markov chain with state-space $\Omega$. Whenever the invariant measure of this chain is absolutely continuous with respect to $P$, law of
large numbers and CLT’s can be deduced, see [17]. For reversible situations, e.g. in the “random conductance model” [19], the invariant measure of the chain \( \{ \omega_n \} \) is known explicitly. In the non-reversible RWRE model, this approach has had limited consequences: one needs to establish absolute continuity of the invariant measure without knowing it explicitly. This was done in [18] for balanced environments, i.e. whenever \( \omega(x,x+e) = \omega(x,x-e) \) \( \text{P.a.s.} \) for all \( e \in \mathbb{Z}^d, |e| = 1 \), by developing a-priori estimates on the invariant measure, valid for every realization of the environment. Apart from that (and very recent work [22]), this approach has not been very useful in the study of RWRE’s.

**Regeneration**

We focus here on another approach based on analogs of hitting times. Throughout, fix a direction \( \ell \in \mathbb{Z}^d \), and consider the process \( Z_n = X_n \cdot \ell \). Define the events \( A \pm \ell = \{ Z_n \rightarrow_n \infty \pm \infty \} \). Then, with \( \text{P} \) a product measure, one shows that \( \text{P}(A_\ell \cup A_{-\ell}) \in \{0,1\} \), [14]. We sketch a proof: Call a time \( t \) fresh if \( Z_t > Z_n, \forall n < t \), and for any fresh time \( t \), define the return time \( D_t = \min \{ n > t : Z_n < Z_t \} \), and say that \( t \) is a regeneration time if \( D_t = \infty \). Then, \( \text{P}(A_\ell) > 0 \) implies by the Markov property that \( \text{P}(A_t \cap \{ D_0 = \infty \}) > 0 \). Similarly, on \( A_\ell \), each fresh time has a bounded away from zero probability to be a regeneration time. One deduces that \( \text{P}(\exists \alpha \text{ regeneration time} | A_\ell) = 1 \). In particular, on \( A \pm \ell \), \( Z_n \) changes signs only finitely many times. If \( \text{P}(A_\ell \cup A_{-\ell}) < 1 \) then with positive probability, \( Z_n \) visits a finite centered interval infinitely often, and hence it must change signs infinitely many times. But this implies that \( \text{P}(A_\ell \cup A_{-\ell}) = 0 \).

The proof above can be extended to non-product \( P \)-s having good mixing properties using, due to the uniform ellipticity, a coupling with simple nearest neighbor random walk. This is done as follows: Set \( W = \{0\} \cup \{ \pm e_i \}_{i=1}^d \). Define the measure

\[
\overline{\text{P}} = P \otimes Q_\varepsilon \otimes \overline{P}_{\ell,\varepsilon}^0 \text{ on } (\Omega \times W^N \times (\mathbb{Z}^d)^N)
\]

in the following way: \( Q_\varepsilon \) is a product measure, such that with \( \varepsilon = (\varepsilon_1, \varepsilon_2, \ldots) \) denoting an element of \( W^N \), \( Q_\varepsilon(\varepsilon_1 = \pm e_i) = \varepsilon/2, i = 1,\ldots, d, Q_\varepsilon(\varepsilon_1 = 0) = 1 - \varepsilon d \).

For each fixed \( \omega, \ell, \overline{P}_{\ell,\varepsilon}^0 \) is the law of the Markov chain \( \{ X_n \} \) with state space \( \mathbb{Z}^d \), such that \( X_0 = 0 \) and, for each \( \varepsilon \in W, \varepsilon \neq 0, \)

\[
\overline{P}_{\ell,\varepsilon}^0(X_{n+1} = z + \varepsilon | X_n = z) = 1_{\{\varepsilon_{n+1} = \varepsilon\}} + \frac{1_{\varepsilon_{n+1} = 0} \omega(z,z + \varepsilon)}{1 - \varepsilon d} - \varepsilon/2 .
\]

It is not hard to check that the law of \( \{ X_n \} \) under \( \overline{P} \) coincides with its law under \( P \), while its law under \( Q_\varepsilon \otimes \overline{P}_{\ell,\varepsilon}^0 \) coincides with its law under \( P_{\ell}^0 \). Now, one modifies the definition of \( D_t \) by requiring that after the fresh time \( t \), the “\( \varepsilon \)” coin was used for \( L_0 \) steps in the direction \( \ell \): more precisely, requiring that \( \varepsilon_{t+i} = u_i, i = 1,\ldots, L \) for some fixed sequence \( u_i \in \mathbb{Z}^d, |u_i| = 1, u_i \cdot \ell > 0 \) such that \( \sum_{i=1}^{L_0} u_i \cdot \ell \geq L/2 \). This, for large \( L_0 \), introduces enough decoupling to carry through the proof, see [29, Section 3.1]. We can now state the:

**Embarrassing Problem 1**: Prove that \( \text{P}(A_\ell) \in \{0,1\} \).

For \( d = 2 \), and \( P \) i.i.d., this was shown in [31], where counter examples using non uniformly elliptic, ergodic \( P \)-s are also provided. The case \( d > 2 \), even for \( P \) i.i.d., remains open.
**Embarrassing Problem 2:** Find transience and recurrence criteria for the RWRE under $P$.

The most promising approach so far toward Problem 2 uses regeneration times. Write $0 < d_1 < d_2 < \ldots$ for the ordered sequence of regeneration times, assuming that $P(A_{d_1}) = 1$. The name regeneration time is justified by the following property, which for simplicity we state in the case $t = e_1$:

**Theorem 3.1 ([28])** For $P$ a product measure, the sequence

$$\left\{ \{\omega_\ell \}_{\ell \in [Z_{d_i}, Z_{d_{i+1} - 1}]}, \{X_\ell \}_{\ell \in [d_i, d_{i+1}]} \right\}_{i=2,3,\ldots}$$

is i.i.d..

From this statement, it is then not hard to deduce that once $E(d_2 - d_1) < \infty$, a law of large numbers results, with a non-zero limiting velocity. Sufficient conditions for transience put forward in [14] turn out to fall in this class, see [28]. More recently, Sznitman has introduced a condition that ensures both a LLN and a CLT:

**Sznitman’s T’ condition: $P(A_{d_1}) = 1$ and, for some $c > 0$ and all $\gamma < 1$,**

$$E(\exp(c \sup_{0 \leq n < d_1} |X_n|^{\gamma})) < \infty.$$  

A remarkable fact about Sznitman’s T’ condition is that he was able to derive, using renormalization techniques, a (rather complicated) criterion, depending on the restriction of $P$ to finite boxes, to check it. Further, it implies a good control on $d_1$, and in particular that $d_1$ possesses all moments, which is the key to the LLN and CLT statements:

$$E\left( \exp \left( \log d_1 \right)^{\delta} \right) < \infty, \forall \delta < 2d/(d + 1).$$

For these, and related facts, see [27]. This leads one to the

**Challenging Problem 3:** Do there exist non-ballistic RWRE’s for $d > 1$ satisfying that $P(A_{d_1}) = 1$ for some $\ell$?

For $d = 1$, the answer is affirmative, as we saw, as soon as $E_P \log \rho_0 < 0$ but $s < 1$. For $d > 1$, one suspects that the answer is negative, and in fact one may suspect that $P(A_{d_1}) = 1$ implies Sznitman’s condition T’. The reason for the striking difference is that for $d > 1$, it is much harder to force the walk to visit large traps.

It is worthwhile to note that the modified regeneration times introduced above using the coupling sequence $\epsilon$ can be used to deduce the LLN for a class of mixing environments. We refer to [4] for details. At present, the question of CLT’s in such a general set up remains open.

**Cut points**
Regeneration times are less useful if the walk is not ballistic. Special cases of non-ballistic models have been analyzed in the above mentioned [18], and using a heavy renormalization analysis, in [2] for the case of symmetric, low disorder, i.i.d. $P$. In both cases, LLN’s with zero speed and CLT’s are provided. We now introduce, for
another special class of models, a different class of times that are not regeneration times but provide enough decoupling to lead to useful consequences.

The setup is similar to that in Theorem 1.4, that is we assume that $d \geq 6$ and that the RWRE, in its first 5 coordinate, performs a deterministic random walk:

For $i = 1, \ldots, 5$, $\omega(x, x \pm e_i) = q_{\pm i}$, for some deterministic $q_{\pm i}$, $P - a.s.$.

Set $S = \sum_{i=1}^{5} (q_i + q_{-i})$, let $\{R_n\}_{n \in \mathbb{Z}}$ denote a (biased) simple random walk in $\mathbb{Z}^3$ with transition probabilities $q_{\pm i}/S$, and fix a sequence of independent Bernoulli random variable with $P(I_0 = 1) = S$, letting $U_n = \sum_{i=0}^{n} I_i$. Denote by $X_n^1$ the first 5 components of $X_n$ and by $X_n^2$ the remaining components. Then, for every realization $\omega$, the RWRE $X_n$ can be constructed as the Markov chain with $X_n^1 = R_{U_n}$ and transition probabilities

$$P^0_\omega (X_{n+1}^2 = z | X_n^1) = \begin{cases} 1, & X_n^2 = z, I_n = 1 \\ \omega(X_n, (X_n^1, z))/(1 - S), & I_n = 0. \end{cases}$$

Introduce now, for the walk $R_n$, cut times $c_i$ as those times where the past and future of the path $R_n$ do not intersect. More precisely, with $P_I = \{X_n\}_{n \in I}$,

$$c_i = \min\{t \geq 0 : P_{(-\infty, t]} \cap P_{[t, \infty)} = \emptyset\}, c_{i+1} = \min\{t > c_i : P_{(-\infty, t]} \cap P_{[t, \infty)} = \emptyset\}.$$

Note that the cut-points sequence depends on the ordinary random walk $R_n$ only. In particular, because that walk evolves in $\mathbb{Z}^3$, it is not difficult to check, following [9], that there are infinitely many cut points, and moreover that they have a positive density. The crucial observation is that the increments $X^{2}_{c_{i+1}} - X^{2}_{c_i}$ depend on disjoint parts of the environment. Therefore, conditioned on $\{R_n, I_n\}$, they are independent if $P$ is a product measure, and they possess good mixing properties if $P$ has good mixing properties. From here, the statement of Theorem 1.4 is not too far. We refer the reader to [1], where this and CLT statements (with 5 replaced by a larger integer) are proved. An amusing consequence of [1] is that for $d > 5$, one may construct ballistic RWRE’s with, in the notations of Section 2, $E_P(v_0(\omega)) = 0$.

**Challenging Problem 4:** Construct cut points for “true” non-ballistic RWRE’s.

The challenge here is to construct cut points and prove that their density is positive, without imposing a-priori that certain components of the walk evolve independently of the environment.

**Large deviations**

We conclude the discussion of multi-dimensional RWRE’s by mentioning large deviations for this model. Call a RWRE nesting if $\omega$ supp$Q$, where $Q$ denotes the law of $\sum_{e \in \mathbb{Z}^d ; |e| = 1} \omega(0, e)$. In words, an RWRE is nesting if by combining local drifts one can arrange for zero drift. One has then:

**Theorem 3.2** ([30]) Assume $P$ is a product nesting measure. Then, for $P$ -almost every $\omega$, $X_n/n$ satisfies a LDP under $P^0_\omega$ with deterministic rate function.

The proof of Theorem 3.2 involves hitting times: let $T_y$ denote the first hitting time of $y \in \mathbb{Z}^d$. One then checks, using the subadditive ergodic theorem, that

$$A(y, \lambda) := \lim_{n \to \infty} n^{-1} \log E^0_\omega (\exp(-\lambda T_{ny}) 1_{\{T_{ny} < \infty\}})$$
exists and is deterministic, for \( \lambda \geq 0 \). In the nesting regime, where slowdown has sub-exponential decay rate due to the existence of traps much as for \( d = 1 \), this and concentration of measure estimates are enough to yield the LDP. We state the

**Embarrassing Problem 5:** Prove the quenched LDP for non-nesting RWRE’s. A priori, non nesting walks should have been easier to handle than nesting walks due to good control on the tail of regeneration times!

**Challenging Problem 6:** Derive an annealed LDP for the RWRE, and relate the rate function to the quenched one.

One does not expect a relation as simple as in Theorem 2.7, because the RWRE can avoid traps by contouring them, and to change the environment in a way that surely modifies the behavior of the walk by time \( n \) has probability which seems to decay at an exponential rate faster than \( n \). We mention in this context that in a related model, RWRE’s on Galton-Watson trees, the quenched and annealed rate functions coincide [6]. We also note that certain estimates on large deviations for RWRE’s, without matching constants, appear in [26].
